The Second ASRA Practice Advisory on Neurologic Complications Associated With Regional Anesthesia and Pain Medicine

Executive Summary 2015

Joseph M. Neal, MD,* Michael J. Barrington, MBBS, FANZCA, PhD,† Richard Brull, MD,‡ Admir Hadzic, MD,§ James R. Hebl, MD,|| Terese T. Horlocker, MD,|| Marc A. Huntoon, MD,** Sandra L. Kopp, MD,|| James P. Rathmell, MD,†† and James C. Watson, MD||

Abstract: Neurologic injury associated with regional anesthetic or pain medicine procedures is extremely rare. The Second American Society of Regional Anesthesia and Pain Medicine Practice Advisory on Neurologic Complications Associated With Regional Anesthesia and Pain Medicine focuses on those complications associated with mechanical, ischemic, or neurotoxic injury of the neuraxis or peripheral nervous system. As with the first advisory, this iteration does not focus on hemorrhagic or infectious complications or local anesthetic systemic toxicity, all of which are the subjects of separate practice advisories. The current advisory offers recommendations to aid in the understanding and potential limitation of rare neurologic complications that may arise during the practice of regional anesthesia and/or interventional pain medicine.

What’s New: The Second American Society of Regional Anesthesia and Pain Medicine Practice Advisory on Neurologic Complications Associated With Regional Anesthesia and Pain Medicine updates information that was originally presented at the Society’s first open forum on this subject (2005) and published in 2008. Portions of the second advisory were presented in an open forum (2012) and are herein updated, with attention to those topics subject to evolving knowledge since the first and second advisory conferences. The second advisory briefly summarizes recommendations that have not changed substantially. New to this iteration of the advisory is information related to the risk of nerve injury inherent to common orthopedic surgical procedures. Recommendations are expanded regarding the preventive role of various monitoring technologies such as ultrasound guidance and injection pressure monitoring. New clinical recommendations focus on emerging concerns including spinal stenosis and vertebral canal pathologies, blood pressure management during neuraxial anesthesia, administering blocks in anesthetized or deeply sedated patients, patients with preexisting neurologic disease, and inflammatory neuropathies. An updated diagnostic and treatment algorithm is presented.

In 2005, the American Society of Regional Anesthesia and Pain Medicine (ASRA) convened a group of experts to develop a practice advisory on neurologic complications associated with regional anesthesia and pain medicine. That initiative resulted in a series of articles published in 2008.6–9 Consistent with ASRA’s commitment to update its practice advisories as new knowledge emerges, the Society convened its second practice advisory in 2012 with the same goal, “to provide information for practitioners of regional anesthesia and pain medicine regarding the etiology, differential diagnosis, prevention, and treatment of neurologic complications.” As before, the current practice advisory focuses on neurologic injuries apart from those caused by hemorrhagic or infectious complications or local anesthetic systemic toxicity, which are the subjects of other ASRA-sponsored practice advisories.7–9 This executive summary condenses findings and recommendations from subtopics of the second practice advisory, which reflects both the proceedings of the conference and interval updates. Practitioners are encouraged to read the supporting articles that accompany this summary; they contain the details on which individual recommendations are based.10–16

“Consistent with a recent editorial call to focus practice advisory and consensus conference updates on new material,17 most supporting articles for individual topics considered by this advisory are built on 2 components. First, to provide perspective, those topics and associated recommendations for which no substantially new knowledge has emerged are reviewed briefly. To provide consistency across time or when appropriate, text and especially recommendations are presented essentially verbatim from those of our original work. The second component focuses on topics that have significantly new information to add to our previous understanding and/or that we felt deserved more extensive discussion than was provided in the first iteration of this advisory.”13

Completely new to the second practice advisory is an in-depth presentation of baseline nerve injury risk inherent to common elective orthopedic surgical procedures.11,12,14 With the growth of registries and their impact on determining accurate and contemporary incidences of complications, the panel added expertise in large epidemiologic studies. Similarly, emerging concerns relating to various ischemia-related neural injuries led to the addition of expert neuroanesthesiologists.

METHODS

The Second ASRA Practice Advisory on Neurologic Complications in Regional Anesthesia and Pain Medicine was...
convened on March 16, 2012, at the Society’s 37th Annual Regional Anesthesiology and Acute Pain Medicine meeting in San Diego, California. The ASRA Continuing Medical Education Committee and Board of Directors approved the first and second advisories. Lead members of the advisory panel presented their summaries in a daylong open forum at the annual meeting. Those advisory panels are listed as authors of this executive summary; additional writers of the individual supporting documents are recognized in the acknowledgments and as individual authors on their articles. Primary panelists were chosen based on their demonstrated expertise in various issues related to neurolologic injury and/or guideline creation. As with our first practice advisory, “panelists received no compensation for their contributions nor did any declare a conflict of interest pertinent to the topic” (Dr Hadzic’s disclosure appears in the attributes). Panelists were charged with performing an extensive review of the literature, summarizing and presenting their findings at the conference, and producing an article based on their scholarly work. During the San Diego conference, panelists and attendees discussed several issues related to neurologic injury in open forum format. All subsequent recommendations were reviewed and approved by members of the panel. Manuscripts were first peer reviewed internally by at least 3 members of the advisory panel and subsequently peer reviewed externally using this journal’s standard peer review process.4

Individual supporting articles10–16 describe the specific search methodology used to research that topic. In general, standard search engines and cross-referenced citations provided the literature basis for the updated material contained within this review.

As paraphrased from our 2008 review, “The strength of scientific evidence that is used to arrive at these recommendations is not easily measured by traditional stratification methodologies such as the Oxford Centre for Evidence-Based Medicine 2011 Levels of Evidence.17 We have used this methodology to rate the level of evidence wherever possible (Appendix 1). However, because of the extreme rarity of the specific complications that are addressed in this article, traditional methodologies such as randomized controlled trials or meta-analyses rarely exist and are unlikely to exist in the future. Our recommendations are therefore based on methodologies that are necessarily less robust, such as anatomic or pathophysiologic studies of human cadavers or animals, nonrandomized trials, retrospective series, case reports, and/or expert opinion. The grading of recommendations offered by this practice advisory has been modified from an American College of Cardiology/American Heart Association construct19 that classifies the strength of guidelines for perioperative cardiac evaluation10–13 (Appendix 2).

“Readers of this manuscript are reminded that practice advisories are created when data on a subject are limited or nonexistent. Advisories rely on limited clinical and animal data and, as such, the synthesis and interpretation of data by 1 group of experts may differ from conclusions by another set of equally qualified experts. Thus, practice advisories represent a level of recommendation that is less than that offered by standards or clinical practice guidelines.20 The recommendations contained herein do not define standard of care. They are not intended to replace clinical judgment as applied to a specific patient scenario. Importantly, in this imperfect setting of controversial topics, limited data, and bias inherent to expert opinion, the Panel consistently tended towards conservative recommendations. These recommendations are intended to encourage optimal patient care but cannot ensure the avoidance of adverse outcomes. As with any practice advisory recommendation, these are subject to revision as knowledge of specific complications advances.”4,13

### INCIDENCES OF NEUROLOGICAL INJURY

The incidence of peripheral nerve injury (PNI) has remained stable in recent decades, despite the introduction of ultrasound guidance.21 The reported frequency of long-term neurologic symptoms after peripheral nerve block using ultrasound guidance22–24 is virtually identical to that reported a decade earlier when peripheral nerve stimulation (PNS) was the primary nerve localization tool.25,26 In both cases, the reported rate of long-term injury is in the 2 to 4 per 10,000 block range. Conversely, accumulating evidence suggests a rising incidence of some catastrophic neuroaxial complications associated with regional anesthetic and interventional pain medicine procedures. Whether these observations signal an absolute increase in complication rates is unclear. The reported increase in neuroaxial complications may reflect more robust registries and improved reporting mechanisms that allow capture of large population data from single countries and institutions and/or databases from health insurers or national quality assurance records.22,27–35 It is also possible that incidences have increased as practitioners extend the limits of neuraxial blockade to sicker, older, and frailer patients who are at an increased risk from their comorbidities. Furthermore, perioperative nerve injury incidence data pertinent to either peripheral or neuroaxial injury can vary widely between reports for a myriad of reasons, including 1) definition of the complication, 2) duration of follow-up, 3) associated risk factors specific to the cohort studied, 4) robustness of data recording (eg, retrospective vs prospective; registries vs quality assurance databases vs insurance company records vs self-report; single institution vs continent-wide); and 5) discriminating the cause of injury (eg, anesthetic vs surgical vs patient vs a combination; transient vs permanent).

### Incidence of Neuroaxial Injury

Neuraxial complications are extremely rare, but when they occur, they often result in life-altering injuries. For instance, there were 127 serious complications in more than 1.7 million neuraxial anesthetics performed during the 1990s in Sweden; 85 (67%) of which resulted in permanent injury.22 The relative occurrence of complications from this report is presented in Table 1. From a medicolegal perspective, closed claims analysis shows that spinal hematomas are the most common cause of neuroaxial injuries that proceed to litigation, and these injuries are often permanent. Conversely, infectious complications have a higher likelihood of at least partial recovery.36

The incidence of neuroaxial injury associated with regional anesthetic techniques varies widely—so much so that it is extremely difficult to cite a meaningful overall risk for injury. Indeed, incidence can even vary among cohorts within the same study. To illustrate this point, the previously noted Swedish study reported vastly different incidences of spinal hematoma—from a risk of 1:200,000 in young women having obstetric epidural blockade to a risk of 1:22,000 in elderly women undergoing hip fracture repair to 1:3600 for those undergoing knee arthroplasty.23 With regard to infectious complications, risks tend to rise in immunocompromised patients, with prolonged epidural catheterization, when the proceduralist unknowingly harbors virulent nasopharyngeal pathogens and does not wear a mask, and/or when practitioners breach aseptic technique.7,28,37–40

Table 2 lists studies reported since 1990 that document incidences of neuroaxial injury (often combining hematoma, infection, direct spinal cord injury, etc). These studies point to several common themes. First, the risk of hematoma is higher with epidural than with subarachnoid techniques. Second, the risk of neuroaxial injury increases when there are associated coagulation abnormalities (whether from disease or intended anticoagulation), increased...

Eight cases of spinal hematoma were associated with thoracic epidural blockade and 17 cases with lumbar epidural blockade. Data from Moen et al.28 Used with permission.

Incidence of PNI

Similar to neuraxial injuries, the reported incidence of PNI associated with regional anesthesia and pain medicine techniques is quite variable. In addition to those factors mentioned for neuraxial injury, the type of peripheral nerve block and its use relative to other blocks may influence injury rate. Because proximal nerves contain a higher proportion of neural tissue as compared with connective tissue,68 it has been speculated that proximal nerve blocks are riskier than more distal approaches. However, there are no convincing data to confirm or refute this notion.22,26,35,69 Evidence strongly suggests that the choice to use a regional anesthetic technique (neuraxial, peripheral, or combined) for total joint arthroplasties does not inherently increase the risk for neurologic injury when compared with general anesthesia alone.70—72 A large retrospective study has also shown that peripheral nerve blocks are not an independent risk factor for perioperative nerve injury.73

In summary, the incidence of perioperative nerve injury is extremely difficult to pinpoint with any degree of accuracy. We have instead chosen to present several different approaches to incidence reporting. The incidence of injury after neuraxial blockade is extremely low, but the injuries are often permanent. Conversely, PONSs after peripheral nerve blockade are common but rarely result in long-term or permanent injury. Complicating this analysis are examples of how individual hospital systems can influence patient outcomes when practices are vigilant, evidence based, and importantly, PNIs are not all block related. For perspective, the overall incidence of perioperative nerve injury in more than 380,000 operations conducted for 10 years at a single institution was 0.03%; perioperative nerve injury was associated with hypertension and smoking but not peripheral nerve block.73

NEUROLOGIC COMPLICATIONS OF ELECTIVE ORTHOPEDIC SURGERIES

New to this practice advisory is a series of articles11,12,14 that explore the rate of neurologic complications related to common elective orthopedic surgical procedures. Knowledge of these injuries and their mechanisms is beneficial for the perioperative physician to ascertain potential etiologies for perioperative neural

Shoulder Surgery

The frequency and etiology of nerve injury associated with shoulder surgery vary by surgical approach. Arthroscopic shoulder surgeries are associated with nerve injury ranging from less than 0.1% to 10%,11 most of which are caused by surgical traction to improve exposure or by arthroscopic portal placement. Shoulder surgeries performed in the lateral decubitus position are associated with transient neuropraxia affecting the operated limb in up to 17% of patients. Patients with stiff shoulders or previous shoulder surgery are at an increased risk.103 The 0.6% to 3.6% incidence of nerve injury associated with reverse total shoulder replacement11 is 11-fold higher than that reported for anatomic shoulder replacement and is primarily related to the permanent arm lengthening associated with that procedure.104

Elbow Surgery

Surgery of the elbow is particularly hazardous because of the minimal soft tissue protection available to the multiple nerves that traverse the joint. Ulnar neuropathy persists in up to 10% of elbow replacement patients.105 Up to 4.2% of elbow arthroscopies are associated with transient iatrogenic nerve injury106 in part because portals are placed blindly in a nerve-rich area.

Hip Surgery

The frequency of nerve injury after total hip arthroplasty (THA) varies widely but generally falls in the 1% range.12 The cause of these injuries is attributed to compression from retractors, traction from intraoperative hip dislocation and manipulation, or excessive leg lengthening. The common peroneal branch of the

deficits, which might include surgical, anesthetic, and patient-related factors (Table 4). In consultation with the operating surgeon and neurologist, the knowledgeable anesthesiologist might facilitate global awareness of possible injury mechanisms, which in turn may optimize postoperative diagnostic and therapeutic interventions. Despite this optimistic goal, determining causation in the setting of concurrent surgery and regional anesthesia is often challenging because of confounding factors such as double-crush injury and/or the technical limitations of diagnostic imaging and neurophysiologic testing. Furthermore, orthopedic surgery literature rarely designates nerve injury as a primary outcome, is often retrospective, and therefore lacks sufficient granularity to fully understand the mechanism of injury. These limitations likely result in underreporting. Thus, although the literature affords a glimpse into the “overall baseline nerve injury” associated with specific surgeries, precise determination of causation is often speculative.

Similar to anesthesia-related injuries, the vast majority of neural injuries associated with orthopedic procedures are transient, yet the rate of long-term injury is of consequence. Most injuries result from a short list of perioperative causes such as direct nerve trauma, positioning, stretch, retraction, or compression from hematoma or dressings. What follows is a brief summary of well-recognized injuries specific to surgery type. To more completely understand this topic, we urge study of the supporting articles and their excellent accompanying illustrations.11,12,14

The incidence of major nerve injury after total knee arthroplasty (TKA) ranges from 0.3% to 9.5%. Two conditions uniquely increase the risk of nerve injury associated with primary THA—developmental dysplasia sometimes requires leg lengthening, which increases the risk 4-fold, whereas revision THA increases the risk 3-fold. The incidence of nerve injury associated with hip arthroscopy ranges from 0.4% to 13.3% and carries with it a unique set of traction-associated risks to the pudendal nerve (from longitudinal traction against the pudendal post) or to the sciatic and femoral nerves.

### Physiologic Factors

- Clinicians are advised to be aware of and to avoid conditions that have been linked to the formation of epidural hematoma or epidural abscess, as noted in previous American Society of Regional Anesthesia and Pain Medicine Practice Advisories. Such conditions include concurrent or imminent anticoagulation, the use of multiple anticoagulants, improper aseptic technique, and needle placement during untreated active infection (Class I).  

Levels of evidence are based on the 2011 Oxford construct.

PNB indicates peripheral nerve block; TSA, total shoulder arthroplasty.

### Foot and Ankle Surgery

Elective foot and ankle surgery using arthroscopy or involving joint replacement is a relatively new field. Literature related to neuraxial neuropathy (spinal stenosis or lumbar radiculopathy). Disruption of the infrapatellar branch of the saphenous nerve and/or the cutaneous nerves of the thigh is quite common but tends to resolve within 2 years. Arthroscopic knee surgeries are associated with frequent (up to 25%) sensory loss to the anterior knee. Similarly, paresthesia from injury to the infrapatellar and sartorial branches of the saphenous nerve is common (up to 75%) after arthroscopic anterior cruciate ligament repair. Inside-out techniques for arthroscopic medial meniscus repair are associated with saphenous nerve injury from direct trauma or suture entrapment.

Levels of evidence are based on the 2011 Oxford construct.

nerve injury in these patients is sparse and mostly retrospective. Iatrogenic injury, especially to cutaneous nerves, seems to be relatively common, albeit mostly well tolerated by patients unless the sensory deficit involves the planter aspect of the foot. Adequate surgical exposure for ankle arthroscopy places all nerves that cross the ankle joint at risk for traction neuropraxia. Cutaneous nerves of the foot are at risk from portal placement or direct surgical trauma during the anterior arthroscopic approach, ankle replacement, or open triple arthrodesis ankle fusion. Fortunately, persistent defects are rare (0.2% at 10 years). Total ankle arthroplasty carries an overall nerve injury rate of 1.3% and most commonly involves the peroneal nerve if the anterior approach is used. Cutaneous nerve sensory deficits after hallux valgus deformity (bunion repair) are poorly documented, and their reported incidence ranges widely.

**Recommendations**

- **Awareness of the causation, location, and frequency of nerve injuries associated with elective orthopedic surgery might assist the anesthesiologist in diagnosis and treatment of perioperative nerve injury. Actual discrimination between surgical, anesthetic, and patient factors is often difficult (Class I).**
- **Differential diagnosis should include prolonged use of a pneumatic tourniquet (>120 minutes), which has been associated with nerve injury. These injuries often present as diffuse sensory-motor deficits (Class I).**
- **Consider delaying placement of regional blocks if assessment of postoperative nerve function is important for the surgeon (Class III).**

**ANATOMY AND PATHOPHYSIOLOGY OF NEURAXIAL INJURY**

Since our 2008 practice advisory, we have expanded recommendations on 5 specific topics that relate to the anatomy and pathophysiology of spinal cord injury associated with regional anesthesia and pain medicine: spinal stenosis, blood pressure control during neuraxial anesthesia, neuraxial injury subsequent to transforaminal techniques, cauda equina syndrome (CES)/local anesthetic neurotoxicity/arachnoiditis, and performing regional anesthetic or pain procedures in patients receiving general anesthesia or deep sedation. Recommendations that remain unchanged from 2008 are summarized in Table 5.

**Spinal Stenosis**

After gaining attention shortly before the creation of our 2008 advisory, evidence has continued to accumulate that suggests an increased risk of spinal cord injury after neuraxial techniques are performed in patients with spinal canal pathology, especially spinal stenosis. These studies suggest a slightly increased rate (compared with institutional norms) of new or worsening neurologic deficits in those patients with known spinal canal pathology who undergo spinal anesthesia. Conversely, studies also report the unexpected discovery of spinal stenosis when (especially elderly women) patients undergo neuroradiography during diagnostic workup for spinal hematoma and CES. It remains unclear if these observations represent cause and effect or simply associate spinal stenosis with the complication. Alternatively, the injuries could have been caused by surgical factors, natural progression of the underlying spinal pathology, or a combination thereof. From a pathophysiologic perspective, spinal stenosis may contribute to spinal injury by reducing the vertebral canal cross-sectional area, thereby inducing spinal cord ischemia via compressive mechanisms and/or by limiting the clearance or free distribution of local anesthetic within the neuraxis, thereby contributing to neurotoxicity. Although the preponderance of these injuries have been associated with epidural or combined spinal-epidural techniques, injuries have also been associated with spinal anesthesia.

As supported by a few large population studies and a multitude of case reports and series, the advisory panel speculates that patients with spinal stenosis may be especially vulnerable to

---

**TABLE 6. Recommendations: Patients With Spinal Stenosis**

These recommendations are intended to encourage optimal patient care but cannot ensure the avoidance of adverse outcomes. As with any practice advisory recommendation, these are subject to revision as knowledge advances regarding specific complications.

- **Spinal stenosis represents a continuum of spinal canal encroachment by hypertrophied ligamentum flavum, bony overgrowth, and/or degenerative changes such as from osteoporosis or herniated nucleus pulposus. Patients with spinal canal pathology (eg, spinal stenosis, lumbar disk disease) may have clinical or subclinical evidence of a preexisting neurologic deficit because of neural compromise from the disease state. However, even moderately severe spinal stenosis is not always symptomatic; many patients (or their health care providers) are unaware that they have the condition (Class I).**
- **When neuraxial anesthesia is complicated by the development of mass lesions within the spinal canal (eg, hematoma or abscess), resultant postoperative neurologic complications may be more likely or more severe in patients with spinal stenosis or other obstructive spinal canal pathology, including changes brought on by patient positioning (Class I).**
- **In patients with known severe spinal stenosis or symptoms suggestive thereof, we recommend that risk-to-benefit be considered before performance of neuraxial anesthesia because of the association of spinal stenosis with neurologic complications in the setting of neuraxial blockade. If neuraxial blockade is performed, we recommend heightened perioperative vigilance for symptoms suggestive of neural compromise (Class II).**
- **There is no firm linkage to injury if spinal stenosis is at a site distant from the level of neuraxial block placement (Class III).**
- **If neuraxial anesthesia is planned, the practitioner may consider reducing the total mass (volume × concentration) of local anesthetic in an effort to reduce segmental spread, local anesthetic neurotoxicity (which is related to concentration), and/or facilitate neurologic assessment by earlier block resolution. Although we are unaware of routinely administered volumes of local anesthetic being associated with injury in patients with spinal stenosis, reports have postulated linkage between high volumes and neuraxial injury in the setting of other mass lesions such as epidural lipomatosis (Class III).**
- **The literature has established an association between spinal stenosis and injury after neuraxial blockade, most often affecting patients in whom the diagnosis of spinal stenosis was made during workup for the injury. There is no clear evidence that spinal stenosis per se caused these injuries (Class II).**
- **Currently, it is unclear whether the development of new or worsening neurologic symptoms after neuraxial anesthesia or analgesia is caused by surgical factors, the anesthetic technique, the natural progression of spinal pathology, or a combination of these factors (Class II).**
neuraxial injury in the concurrent settings of preexisting neuraxial disease, non-neutral positions during the perioperative period (eg, hyperlordosis or extreme lateral flexion), or other conditions that compete with the spinal cord for space within the vertebral canal, for example, epidural hematoma or abscess, spinal arachnoid cyst, or ankylosing spondylitis (Fig. 1). When the diagnosis of moderate-to-severe spinal stenosis is known, we recommend consideration of the risk versus benefit of a neuraxial technique. If such a technique is chosen, we suggest increased vigilance for signs of postoperative neurologic compromise. Finally, we acknowledge that significant spinal stenosis is common (19% prevalence in patients in their sixties118) and often unrecognized by both patients and their health care providers. The majority of patients with spinal stenosis tolerate neuraxial blockade without clinically apparent injury. Nevertheless, the panel advises that increased reporting of neuraxial injury in the setting of spinal stenosis should elevate the anesthesiologist’s awareness of this disease process. Our recommendations regarding spinal stenosis are presented in Table 6.

Blood Pressure Control During Neuraxial Anesthesia

The current advisory places increased emphasis on the importance of avoiding prolonged hypotension during neuraxial anesthetics (>20%–30% below baseline mean arterial pressure [MAP] especially for 20 minutes or longer).13 We base this recommendation on evolving knowledge that the lower limit of autoregulation (LLA) for cerebral and spinal cord blood flow (SCBF) is likely higher than previously believed and ongoing case reports and medicolegal experience wherein patients have suffered spinal cord ischemia or infarction in the setting of prolonged hypotension or hypoperfusion.

Perioperative spinal cord ischemia or infarction is an extremely rare event that is most often associated with specific surgeries (aortic, cardiac, spine). Other risk factors for spinal cord infarction include those classically recognized for vascular disease, that is, atherosclerosis, hypertension, and tobacco abuse. An insult to the spinal cord circulation that is sufficient to cause ischemia or infarction implies either mechanical injury to the spinal vasculature, an embolic event, or hypoperfusion, as may occur during prolonged periods of hypotension. Recent data and opinion suggest that the LLA for SCBF is likely closer to a MAP of 60 to 65 mm Hg rather than the classically understood MAP of 50 mm Hg.119,122 Moreover, direct and surrogate measures of the LLA for cerebral blood flow in humans suggest that the LLA varies widely among subjects and, contrary to common belief, is usually not related to or predicted by baseline blood pressure.121 There exists a “physiologic reserve” between the LLA and the blood pressure at which cellular injury or death actually occurs. Clinical experience suggests that the vast majority of patients whose blood pressure is low during a neuraxial technique do not suffer spinal cord ischemic injury most likely because 1) the blood pressure is not critically low for that individual (ie, the blood pressure is higher than that patient’s LLA or within their physiologic reserve) and/or 2) limited duration at the lower blood pressure. However, case reports also reveal that an extremely small subset of patients either have a higher set point for their personal LLA and/or cannot withstand prolonged periods of “low-normal” blood pressure. Moreover, the risk for ischemic injury is likely increased in these patients when hypotension is interposed with other factors that may compromise SCBF, such as vascular stenosis, embolic phenomena, non-neutral spinal column positioning (eg, hyperlordosis, extreme lateral flexion, or lithotomy), hypocapnia, raised intrathoracic pressure, and/or surgical retraction.

The extreme rarity of perioperative ischemic spinal cord injuries makes it impossible to assume cause and effect in those patients identified with concurrent periods of hypotension particularly when the degree of hypotension is not extreme and/or of extreme duration. Nevertheless, because the chance for recovery after spinal cord infarction is dismal and the ability to predict an individual patient’s LLA is clinically difficult if not impossible, the panel “recommends that anesthesiologists strive to maintain blood pressure within 20% to 30% of baseline and that persistent hypotension be treated.”111 If an ischemic injury is suspected, immediate neuroimaging is necessary to rule out a potentially treatable condition, such as spinal hematoma or abscess. If such a condition is excluded, the panel recommends normalizing or increasing the patient’s blood pressure to high-normal range and considering cerebrospinal fluid (CSF) drainage. The role of corticosteroids specifically for anesthesia or pain medicine–related injuries is unknown. The use of corticosteroids may be beneficial in instances of direct spinal cord trauma from interventional procedures. Conversely, the known linkages to worsened neurologic outcome from direct corticosteroid-induced neurotoxicity and indirect hypoglycemia lead us to recommend avoiding corticosteroids when spinal cord ischemia is suspected. In either case, maintain normoglycemia by using insulin in those patients with elevated glucose levels. These decisions are best made in consultation with neurological colleagues. Recommendations for the diagnosis and treatment of spinal cord ischemia or spinal cord infarction are presented in Table 7.

Transformaminal Pain Medicine Procedures

Our 2008 practice advisory3,4 made recommendations regarding the then emerging awareness of catastrophic neurologic injuries associated with transformaminal pain medicine procedures. In the interim, a collaboration took place between the US Food and Drug Administration Safe Use Initiative and a group with representation from specialties with expertise in interventional treatment of spinal disorders.123 This initiative puts forth a series of expert opinions meant to improve patient safety during the provision of transformaminal procedures. In addition, a number of case reports and small series continue to describe infarctions of the spinal cord, brainstem, cerebrum, or cerebellum after both cervical124,125 and lumbar126,127 transformaminal injections. More evidence for the role of particulate steroids in these injuries has come forth, including reports that the effectiveness of nonparticulate steroid preparations, such as dexamethasone, may be similar to that of particulate preparations.128–130 Our previous recommendations regarding transformaminal injections have been modified based on these studies plus the US Food and Drug Administration Safe Use Initiative and are presented in Table 8.

Cauda Equina Syndrome

Injury to the cauda equina manifests as bowel and bladder dysfunction with various degrees of bilateral lower extremity weakness and sensory impairment. There are multiple etiologies for CES, ranging from neural element compression from hematoma, abscess, or herniated intervertebral discs to poorly understood
FIGURE 1. Extradural mass lesions. Note how various conditions can reduce spinal canal cross-sectional area and either directly compress the spinal cord or the cauda equina (arrows) or increase epidural space or cerebrospinal fluid pressures through their mass effect. Illustration by Gary J. Nelson. Reproduced with permission from Neal and Rathmell, Complications in Regional Anesthesia and Pain Medicine.117
The role of corticosteroids in anesthesia-related injuries is unknown. Corticosteroids may have a beneficial effect after direct spinal cord inflammation in response to the local anesthetic, adjuvant, needle proper doses of local anesthetic and/or who develop neural injury. These pathophysiologic explanations for CES, there seems to exist a poor predictor of LLA except at the extremes of hypertension, for example, systolic pressure >160 mm Hg (Class II). When neuraxial anesthesia or analgesia is followed by unexpectedly prolonged sensory or motor blockade, recrudescence of weakness or sensory presentations associated with normal clinical settings. Known risk factors for anesthetic-related CES are supernormal doses of intrathecal local anesthetic and/or the maldistribution of local anesthetic spread within the intrathecal space. In recent years, reported cases of CES have been associated with previously undiagnosed spinal stenosis. In theory, a tight spinal canal may lead to pressure-induced spinal cord ischemia or limit normal local anesthetic distribution within the intrathecal sac, thereby exposing the cauda equina to high drug concentrations. Either of these conditions could promote local anesthetic neurotoxicity and could be exacerbated by additional compromise of the spinal canal, as may occur with non-neutral surgical positioning. In addition to these pathophysiologic explanations for CES, there seems to exist a subset of patients who suffer CES after receiving a standard neuraxial anesthetic. The advisory panel speculates that these patients might represent an extremely rare subset of patients who are predisposed to neurotoxicity from clinically appropriate doses of local anesthetic and/or who develop neural inflammation in response to the local anesthetic, adjuvant, needle trauma, surgical positioning, or factors unrelated to the anesthetic.

Table 9 presents our recommendations regarding CES, which include risk-to-benefit consideration of neuraxial anesthesia in patients with known severe lumbar spinal stenosis, and to avoid exceeding the maximum recommended dose of intrathecal local anesthetic in the setting of a failed, partial, or maldistributed spinal anesthetic.

Local Anesthetic Neurotoxicity

Controversy remains as to whether transient neurologic symptoms (TNS) after spinal anesthesia are a form of local anesthetic neurotoxicity. Regardless, since the 2008 advisory, further clinical experience has come forth concerning TNS and intrathecal 2-chloroprocaine (2-CP). These studies suggest that the risk of TNS is very low when using 40 to 50 mg intrathecal 2-CP. Spinal 2-CP remains off-label in the United States; in 2013, a 1% 2-CP solution was approved for intrathecal use in Europe. Although the risk of TNS from 2-CP is low, there is insufficient data for the advisory panel to make recommendations with regard to 2-CP and CES. Indeed, 1 patient who received 2-CP in a recent study developed a transient case of incomplete CES that was confirmed by positive nerve conduction study and electromyography.

Arachnoiditis

New to this iteration of the practice advisory is a discussion regarding arachnoiditis. This poorly understood diffuse inflammatory reaction of the meninges is classically associated with nonanesthetic conditions, such as infection, trauma, contrast media, or multiple back surgeries. Cases of arachnoiditis that stem directly from a neuraxial anesthetic, if they exist, are extremely rare and most likely related to an idiosyncratic reaction to an unknown provocation. Nevertheless, concern has recently been
TABLE 8. Recommendations: Transforaminal Injection Techniques

These recommendations are intended to encourage optimal patient care but cannot ensure the avoidance of adverse outcomes. As with any practice advisory recommendation, these are subject to revision as knowledge advances regarding specific complications.

- To avoid direct injection into critical structures, final position of an immobile needle during transforaminal injection should be confirmed by injecting contrast medium under real-time fluoroscopy and/or digital subtraction imaging, using adequate radiologic views, before injecting any substance that may be hazardous to the patient (Class III).
- Because of the significantly higher risk of catastrophic neurologic injuries associated with cervical transforaminal injections, particulate steroids should not be used in therapeutic cervical transforaminal injections (Class III).
- Although the risk of neurologic injury is markedly lower when performed at lumbar levels, a nonparticulate steroid (eg, dexamethasone) should be used for the initial injection in lumbar transforaminal epidural injections (Class III).
- Particulate steroids can be considered under some circumstances for lumbar transforaminal injections, for example, after failure to respond to treatment with a nonparticulate steroid (Class III).

TABLE 9. Recommendations: CES, Local Anesthetic Neurotoxicity, and Arachnoiditis

These recommendations are intended to encourage optimal patient care but cannot ensure the avoidance of adverse outcomes. As with any practice advisory recommendation, these are subject to revision as knowledge advances regarding specific complications.

- Initial dosing or redosing of subarachnoid local anesthetic in excess of the maximum recommended dose may increase the risk of spinal cord or spinal nerve root neurotoxicity and should be avoided. In addition, maldistribution (usually sacral) of local anesthetic spread should be ruled out before redosing single-injection or continuous subarachnoid blocks (Class I).
- The risks and benefits of neuraxial techniques should be considered in patients known to have moderate-to-severe spinal stenosis, especially if within the vertebral territory of the intended injection (Class II).
- The incidence of TNS after 40 to 50 mg intrathecal 2-chloroprocaine seems to be remarkably low. The number of 2-chloroprocaine spinal anesthetics reported in the literature is insufficient to determine the risk for CES or other manifestations of neurotoxicity (Class III).
- Physically and temporally separate disinfectant use from block trays and instruments during neuraxial procedures. Allow the solution to completely dry on skin before needle placement (2–3 min). Care should be taken to avoid needle or catheter contamination from chlorhexidine spraying or dripping, or from applicator device disposal, onto aseptic work surfaces (Class II).

ANATOMY AND PATHOPHYSIOLOGY OF PNI

The pathophysiology and etiology of PNI associated with regional anesthetic techniques are exquisitely complex topics. Yet understanding these mechanisms is crucial if anesthesiologists are to develop risk avoidance strategies. Since the 2008 practice advisory, further studies have added to our understanding of how peripheral nerve microanatomy influences PNI. Similar knowledge gains have occurred regarding the relative roles of nerve localization and monitoring technologies. Although the next section of this article will summarize existing and new knowledge.

Procedures on Anesthetized or Deeply Sedated Patients

One of the more controversial recommendations from our previous advisory concerns performing regional anesthetics or interventional pain medicine procedures on patients receiving general anesthesia or who are “deeply sedated to the point of being unable to recognize and/or report any sensation that the physician would interpret as atypical during block placement.” This topic is a good example of how groups of equally qualified experts can analyze the same limited data set and arrive at different advices, as is the case with North American and European interpretations of this topic. In the interim since our last advisory, a number of large registries from the United States and Europe have reaffirmed our previous recommendation that placing peripheral and neuraxial nerve blocks in anesthetized children seems not to increase injury above baseline risk estimates (which are derived mostly from studies of awake adults). Similarly, a report from the ASA Closed Claims study pointed to an apparent increased injury rate in those patients who underwent cervical interventional pain medicine procedures while anesthetized or deeply sedated. We believe that this report also reaffirms our previous advice not to routinely perform regional anesthetic or interventional pain medicine procedures in anesthetized or deeply sedated adult patients. Despite the controversy surrounding this topic, the panel views wakefulness as yet another monitor of patient well-being during procedural interventions and as such suggests that wakefulness could be considered a component of vigilant patient care, just as ultrasound guidance, PNS, and expert observation are. Recommendations for performing procedures on anesthetized or deeply sedated patients are presented in Table 10.
related to nerve injury pathophysiology, readers who desire a more complete understanding of this complicated topic are referred to the detailed supporting article contained within this series.10

Anatomic Considerations

Anesthesiologists are increasingly aware of the importance of peripheral nerve microanatomy as a key determinant of PNI risk. Nerve axons are bundled as fascicles and enveloped within the perineurium, which consists of layers of tightly fitting perineurial cells that prevent diffusion of potentially toxic substances into the fascicle and also partially protect against mechanical injury. Multiple fascicles are surrounded by a permeable epineurium, which contains the fascicles plus various amounts of interfascicular connective tissues that occupies an ever-increasing proportion of the nerve’s cross-sectional area as the nerve extends proximally to distally. This relative abundance of distal connective tissue explains why intraneural, but extrafascicular, needle tip placement is more likely to reside in a noncritical (ie, nonfascicular) portion of the nerve. Thus, neural microanatomy seems to correlate with ultrasound-enabled clinical observations that block needles were intraneural (subepineurium, but extraperineurium) more often than was previously assumed, but that this unanticipated occurrence was not associated with clinical evidence of PNI in most patients.136

Pathophysiology of PNI

The traditional mechanisms of PNI have been described in animal models as mechanical, injection, ischemic, and/or neurotoxic.

<td><strong>• Monitoring and Prevention:</strong> There are no data to support the concept that ultrasound guidance of needle placement reduces the risk of neuraxial injury in patients under general anesthesia or deep sedation (Class II).</td>
</tr>
<tr>
<td><strong>• Adult Neuaxis:</strong> Warning signs such as paresthesia or pain on injection of local anesthetic inconsistently herald needle contact with the spinal cord. Nevertheless, some patients do report warning signs of needle-to-neuraxis proximity. General anesthesia or deep sedation removes any ability for the patient to recognize and report warning signs. This suggests that neuraxial regional anesthesia or interventional pain medicine procedures should be performed rarely in adult patients whose sensorium is compromised by general anesthesia or deep sedation. Adult patients with specific conditions (eg, developmental delay, multiple bone trauma) may be appropriate exceptions to this recommendation after consideration of risk vs benefit (Class III).</td>
</tr>
<tr>
<td><strong>• Pediatric Neuaxis:</strong> The benefit of ensuring a cooperative and immobile infant or child likely outweighs the risk of performing neuraxial regional anesthesia in pediatric patients during general anesthesia or deep sedation. The overall risk of neuraxial anesthesia should be weighed against its expected benefit (Class I).</td>
</tr>
</tbody>
</table>

*Anesthetized refers to patients under general anesthesia. Deep sedation is defined as the patient being sedated to the point of being unable to recognize and/or report any sensation that the physician would interpret as atypical during block placement.

Recommendations contained within Table 10 have been modified from our 2008 advisory.1 Significant changes are in italics.

Levels of evidence are based on the 2011 Oxford construct.18
Forceful needle-to-nerve contact and/or injection into the nerve are believed to set in motion a series of events that might lead to ischemia or neurotoxicity. Needle trauma to or rupture of the perineurium is believed to negate the fascicle’s protective environment, which then becomes a crucial contributory factor in determining the likelihood and severity of subsequent PNI. Direct application of otherwise innocuous local anesthetic to denuded axons can cause acute inflammatory reactions or neurotoxicity. Such insults are magnified in the setting of a disrupted perineurium and prolonged exposure to the local anesthetic (as might occur with vasocstrictive adjuvants, which reduce drug clearance). If the needle does not completely disrupt the perineurium, injection can transiently elevate intraneural pressure and lead to ischemia. Bleeding around the nerve or microhematoma within the nerve can also lead to ischemia. Lastly, nonspecific inflammatory responses can affect single or multiple nerves and at sites proximate to or distant from the surgical site. Such inflammatory changes have been observed during surgical nerve bypass procedures for permanent phrenic nerve injuries associated with interscalene block.

Etiology of PNI
The etiology of PNI continues to evoke explanations that include anesthetic, surgical, patient-related, or a combination of factors thereof. The evidence for the significance of these factors is summarized in Table 4.

Anesthetic Risk Factors
Recent large studies fail to link peripheral nerve block as an independent risk factor for perioperative nerve injury either in the general operative setting or in total joint arthroplasties. Nevertheless, PNI does occur as a consequence of anesthetic techniques. Controversy continues regarding the concept of intentional intraneural injection for the purpose of achieving more rapid onset of denser peripheral nerve blockade. Published reports of intentional intraneural injection have noted no nerve injuries, albeit in patient numbers too small to prove safety. Similarly, several small clinical studies have also reported no PNI despite unintentional intraneural injection. Nevertheless, the advisory panel interprets the majority of animal and human PNI studies as supporting the concept that anesthesiologists should not purposefully seek needle-to-nerve contact or intentional intraneural injection.

Surgical Risk Factors
Most surgical injuries are thought to occur from traction, stretch, transection, or compression injuries. These factors were reviewed in the previous section on surgically related neurologic complications.

Patient Risk Factors
Factors that place patients at an increased risk for anesthesia-related PNs include metabolic, hereditary, toxic, and entrapment neuropathies and other preexisting neurologic injuries/conditions. Diabetic neuropathy is of particular concern because it seems to increase PNI at least 10-fold as compared with the general population. A large general surgical population study identified peripheral vascular disease, smoking, vasculitis, and hypertension as independent risk factors for perioperative nerve injury.

The Role of Nerve Localization and Monitoring Techniques
Paresthesia
A single randomized clinical trial did not support the elicitation of paresthesia as a risk factor for PNI. The absence of a paresthesia does not reliably exclude the possibility of needle-to-nerve contact nor does it prevent PNI. Nevertheless, severe paresthesia that occurs with needle advancement or injection should prompt the cessation of either maneuver, and repositioning of the needle should be considered.

Peripheral Nerve Stimulation
Peripheral nerve stimulation is characterized by low sensitivity, but high specificity, for needle-to-nerve contact. When a motor response occurs at a low current output, such as 0.2 mA or lower, one cannot reliably discern if the needle tip is abutting the nerve or is subpialnerve. Conversely, current output greater than 0.5 mA is generally associated with extraneural needle placement, although reports exist of intraneural needle tip placement at currents approaching 2.0 mA.

Injection Pressure Monitoring
Interest continues in the controversial practice of injection pressure monitoring. The clinical usefulness of this monitoring modality remains poorly defined. Avoidance of high resistance to injection seems to be a reasonable strategy during peripheral nerve blockade because studies consistently show that low opening pressures (~15 psi) are associated with injection into non-neural tissues. However, injection pressure monitoring seems to be most valuable as a negative predictor of PNI, that is, low injection pressure correlates with no PNI, but high injection pressure is not consistently linked to PNI. Unfortunately, anesthesiologists cannot reliably discern injection pressure based on syringe feel alone. With regard to direct pressure monitoring systems, studies suggest that the technique cannot reliably detect intraneural infrasacellar injection and that needle-to-nerve contact and infrasacellar injection can be indistinguishable from each other.

Ultrasound Guidance
Ultrasound guidance has not been associated with a reduction of PONS or long-term PNI. The inability of ultrasound to reduce nerve injury may stem from technical and/or training limitations in discerning nerve from surrounding tissues (insufficient resolution to distinguish fascicles from connective tissue) or it may be related to anesthesiologists attempting to place the needle as close to the nerve as possible, thereby potentially increasing the risk for unintended subpialnerve injection. Recent studies suggest that injecting local anesthetic adjacent to the brachial plexus, rather than within the fascial sheath, results in equivalent neural blockade.

In summary, PNI is a diverse and complicated entity that may be associated with anesthetic, surgical, patient-related, or a combination of risk factors. In recent years, ultrasound studies have demonstrated that anesthesiologists place block needles within the nerve much more frequently than previously imagined and that most of these occurrences are not associated with PNI. The practice advisory panel interprets the weight of animal and human evidence to support the practice of avoiding needle placement that abuts or enters the nerve. Although there is no evidence that PNS, ultrasound, or pressure monitoring can prevent PNI, the panel believes it reasonable to consider using several of these modalities in combination when appropriate. Our advice is tempered by our limited knowledge of those factors that most influence PNI and recognition that those factors vary with the specific nerve involved, the peripheral block performed, and with unique patient and surgical factors. Recommendations regarding nerve localization techniques are presented in Table 11.

PATIENTS WITH PREEXISTING NEUROLOGIC DISEASE

The “double-crush” theory was first proposed by Upton and McComas in 1973. The theory maintains that patients with preexisting neurologic compromise anywhere along the neural pathway may be at increased susceptibility for subsequent nerve injury from a secondary low-grade insult such as might occur during the perioperative period from surgery or anesthetic causes. Moreover, the resultant nerve damage may exceed the additive effects of 2 low-grade injuries (Fig. 2). Preexisting neurologic conditions, many of them subclinical, might set the stage for subsequent double-crush scenarios, including such broad etiologies as mechanical, ischemic, toxic, metabolic, and autoimmune conditions. Preexisting neurological conditions have historically led to recommendations not to perform regional anesthetics. The intent of our practice advisory was to analyze and summarize current evidence so that clinicians and their patients can make better informed decisions when presented with the conundrum of whether or not to offer regional anesthetic or interventional pain medicine procedures to patients with preexisting neurologic disease.

Although new information on the issue of performing regional anesthetic techniques in patients with preexisting neurologic disease is limited, this evidence reinforces our previous recommendations regarding patients with diabetes mellitus and spinal stenosis. Furthermore, there is a substantial amount of new information on postsurgical inflammatory neuropathies (PSINs). More detailed discussion on the topic of performing blocks in

FIGURE 2. Neural lesions resulting in denervation. Axoplasmic flow is indicated by the degree of shading. Complete loss of axoplasmic flow results in denervation (C, D, E). A, Normal neuron. B, Mild neuronal injury at a single site (x) is insufficient to cause denervation distal to the insult. C, Mild neuronal injury at 2 separate sites (x1 and x2) may cause distal denervation (ie, “double crush”). D, Severe neuronal injury at a single site (X) may also cause distal denervation. E, Axon with a diffuse preexisting underlying disease process (toxic, metabolic, ischemic) may have impaired axonal flow throughout the neuron, which may or may not be symptomatic, but predisposes the axon to distal denervation after a single minor neural insult at x (ie, “double crush”). By permission of Mayo Foundation for Medical Education and Research.
patients with preexisting neurologic disease is contained in the supporting article by Kopp et al.16

Preexisting Peripheral Nervous System Disorders

Peripheral neuropathies are either hereditary or acquired. The most common inherited disorders are from the collective category of Charcot-Marie-Tooth (CMT) disease, which affects approximately 1 in 2500 humans. A few case reports and small case series describe the use of either peripheral or central regional anesthetic techniques in CMT patients without apparent worsening of their underlying condition. However, clinical evidence is too sparse to allow for definitive recommendations other than if a regional technique is chosen; extra precautions should be taken to minimize other surgical or anesthetic risk factors. Most patients with preexisting peripheral nervous system disease have acquired peripheral neuropathies such as diabetes mellitus or chemotherapy-induced neuropathies.

Diabetic Polyneuropathy

Diabetes mellitus is associated with several types of neuropathies, but distal symmetric sensorimotor polyneuropathy (diabetic polyneuropathy or DPN) is most common and is present in up to 50% of long-standing diabetic patients. Although animal studies155,156 consistently report that diabetic nerve fibers are more sensitive to the blocking effects of local anesthetics and may have increased susceptibility to local anesthetic neurotoxicity, it is unclear if these findings are clinically relevant in humans. A small number of clinical studies attest to higher peripheral nerve block success rates in diabetic patients,157 but such increased sensitivity to local anesthetics may not necessarily reflect increased susceptibility to neurotoxicity. However, a single-institution study reported that 0.4% (95% CI, 0.1%–1.3%) of patients with sensorimotor neuropathy or DPN who underwent spinal anesthesia subsequently developed new or progressive postoperative neurologic deficits, which is a higher incidence than that observed in the institution’s general surgical population.49 Although this finding does not absolutely link spinal anesthesia to increased risk in patients with DPN, it does suggest that the anesthetic may have been a contributing factor. Another area of concern in patients with DPN involves nerve localization technique; diabetic nerves are less sensitive to electrical stimulation, which theoretically increases the risk of intraneural needle placement when localizing nerves using a PNS.158 Although ultrasound guidance has not decreased the rate of PONS in the general population, it is possible that the advantages of ultrasound guidance—facilitating avoidance of intentional needle-nerve contact and reducing local anesthetic volume—may eventually prove beneficial in at-risk populations such as diabetic patients.21 In summary, patients with DPN may be more susceptible to double-crush injury, but current clinical evidence is suggestive rather than definitive. Nevertheless, we recommend that, in profoundly symptomatic patients, consideration be given to limiting local anesthetic concentration and/or dose, avoidance of adjuvant epinephrine,159 and ultrasound guidance to maintain needle tip distance from the nerve.

Chemotherapy-Induced Neuropathy

Approximately 30% to 40% of patients who receive neurotoxic chemotherapeutic agents (eg, cisplatin, vincristine, paclitaxel) develop peripheral neuropathy. The risk of nerve injury is increased further in those patients with preexisting neurologic changes from diabetes mellitus or alcoholism. Many of these chemotherapy-induced neuropathies are subclinical. A note of concern pertinent to these patients was raised by an isolated case report of severe brachial plexopathy after peripheral nerve blockade in a patient with subclinical chemotherapy-induced neuropathy.160

Inflammatory Neuropathies

The inflammatory neuropathies include Guillain-Barré syndrome (GBS) and recently highlighted postsurgical inflammatory neuropathies (PSIN). Most case reports of GBS come from (usually successful) use of neuraxial blockade in obstetric patients. However, major concerns include the potential for autonomic instability and consequent exaggerated responses to neuraxial blockade and reactivation of previously dormant GBS symptoms, both of which have been reported.10 There are too few data to make recommendations on GBS and concurrent regional anesthetic techniques other than to suggest that decisions be made on an individualized basis that accounts for risk and benefit.

Postsurgical Inflammatory Neuropathies

There is growing awareness of inflammatory etiologies for perioperative nerve injuries, including Parsonage-Turner syndrome,161 lumbosacral radiculoplexus neuropathies,162 and PSIN.163,164 Distinguishing features of these neuropathies include their delayed appearance (within 30 days of surgery, although some may be apparent immediately), which is usually followed by a period of normal recovery. Clinical presentation also includes signs and symptoms outside of the expected location of anesthetic blockade or surgery and a period of intense pain out of proportion to what would be expected from the surgery, which then resolves, only to be followed by weakness. Postsurgical inflammatory neuropathy is thought to be an immune-mediated idiopathic response to a physiologic stress, such as infection, vaccination, or surgery.164 The associated neurologic deficits may be focal, multifocal, or diffuse. The greatest risk of PSIN is surgeons and anesthesiologists not considering its diagnosis and, in so doing, delaying potentially useful therapies. When patients present with this constellation of symptoms, urgent neurological consultation is warranted. Although the natural history without treatment is one of probable slow recovery, once diagnosed, many neurologists recommend suppressing the immune response with prolonged high-dose steroids or immunoglobulin to minimize the immune-mediated nerve injury, although such therapies have not been proven. In contradistinction from much perioperative nerve injury, most patients with PSIN improve with treatment if diagnosed early.

Preexisting Central Nervous System Disorders

As with preexisting peripheral nervous system disease, anesthesiologists historically were reluctant to offer regional anesthetic–based techniques to their patients with preexisting CNS diseases.154 Although modern data are limited, most studies of the general surgical population159 and obstetrics165,166 have not found that regional techniques place most patients with active disease at risk for new or worsening symptoms. Despite these reassuring findings, the decision to perform neuraxial anesthetic or interventional pain medicine procedures in patients with preexisting CNS disease still demands risk-to-benefit consideration.

Multiple Sclerosis

The focal demyelination that characterizes multiple sclerosis (MS) contributes to its classic “waxing and waning” pattern. When coupled with known perioperative stressors that can worsen the disease process, such as hyperpyrexia, infection, and/or emotional stress, it is often difficult to sort out the causes for perioperative progression or new onset of MS-related symptoms. Although classically considered a CNS disease, some portion of patients (from 5% to 47%)167,168 have also peripheral demyelination. The clinical significance of peripheral MS is unclear because there are very few case reports that link MS to injury after peripheral nerve blockade.169 Conversely, there are case series that support the
general safety of neuraxial anesthesia in parturients with MS.\textsuperscript{165,170} Importantly, the obstetric model may not be ideal because MS patients have diminished frequency of relapse during pregnancy but an increased rate postpartum. To maximize safety in obstetric patients, it is recommended that the dose and concentration of local anesthetic be limited. Epidural anesthesia is considered safer than spinal anesthesia because it does not deposit local anesthetic directly adjacent to the CNS (ie, the spinal cord).

**Postpolio Syndrome**

Postpolio syndrome (PPS) is the most prevalent motor neuron disease in North America. The largest series (n = 79) of PPS patients to receive neuraxial anesthesia documented no worsening of symptoms.\textsuperscript{56} Nevertheless, the paucity of data on these patients suggests that the risk and benefit of a neuraxial technique be balanced against that of general anesthesia.

**Amyotrophic Lateral Sclerosis**

The greatest perioperative risks of amyotrophic lateral sclerosis (ALS) are respiratory and/or neurologic deterioration. A few case reports attest to the apparent safety of neuraxial or peripheral blockade in ALS patients,\textsuperscript{48} but these reports are insufficient for general recommendations. As with other CNS preexisting diseases, the risk and benefit of regional techniques should be balanced against those of general anesthesia.

**Spinal Canal Pathology**

Emerging concerns regarding patients with spinal stenosis were discussed in the section on neuraxial pathophysiology.\textsuperscript{13} With regard to previous spine surgery, a recent publication reported no evidence that these patients were at risk for developing new or progressive neurologic deficits when they underwent spinal anesthesia.\textsuperscript{58} Although previous spinal surgery should not be considered a contraindication to neuraxial anesthesia or interventional pain medicine techniques, consideration might be given to preprocedure imaging to better define relevant anatomy, deformity, and/or surgical implants.\textsuperscript{58}

**Neural Tube Defects**

Congenital neural tube defects may present at birth as open spinal dysraphisms (eg, meningocoele or meningo(myelo)cele) or closed spinal dysraphisms, which range from isolated defects of posterior vertebral column closure (spina bifida occulta) or more serious malformations such as diastematomyelia (split cord malformations), tethered spinal cord syndrome, or dural ectasia (lumbosacral widening or caudal displacement of the dural sac). A few case reports have described successful spinal or epidural anesthesia in parturients who previously underwent surgical correction of open spinal dysraphisms. These cases were characterized by extensive cranial spread of a dense local anesthetic block, with limited caudad spread below the site of surgical correction. Thus, if the decision is made to provide neuraxial anesthesia in this subset of patients, it is recommended that the block needle be inserted cephalad to the original lesion.\textsuperscript{165}

The closed spinal dysraphisms are challenging because the proceduralist or patient may not always be aware of the defect. Failure of a single vertebral arch to fuse (isolated spinal bifida occulta) is common in the general population (10%–24%).\textsuperscript{171} It is recommended that needle insertion occur above the level of spinal abnormality, assuming its presence is known. A total of 11 cases of successful epidural anesthetics using normal doses of local anesthetic have been reported in isolated spina bifida patients.\textsuperscript{16} In contrast, patients with complex spina bifida should not receive neuraxial anesthesia. This recommendation is based on reports of neurologic complications in patients who underwent a variety of neuraxial techniques; in some of those cases, the defect was unrecognized before the procedure. Patients with complex spina bifida often have associated conditions, such as cutaneous manifestations over the level of abnormality, involvement of more than 1 lamina, or associated bowel, bladder, or neurologic symptoms. If the presence of a neural tube defect is known or suspected, the underlying neuroanatomy should be documented with radiographic imaging before considering a neuraxial technique. We recommend that complex closed spinal dysraphisms be considered a contraindication to neuraxial techniques. In patients with spina bifida occulta, neuraxial techniques may be considered after appropriate risk (technical difficulties, dural puncture, or atypical local anesthetic spread) is balanced against perceived benefit.

Recommendations for performing neuraxial or peripheral anesthesia/analgesia procedures in patients with preexisting neurologic disease are presented in Table 12.

**DIAGNOSIS AND TREATMENT**

Since our 2008 advisory, new information has evolved concerning postoperative inflammatory neuropathies. We have added new information on acute interventions that may possibly improve neurologic outcome, both acutely and in relation to long-term management of the neuropathic pain that occasionally results from these injuries. We have updated our previous algorithm that contains a structured approach to diagnosis and initial management (Fig. 3). Although this advisory focuses on nonhemorrhagic and noninfectious neurologic complications, these entities will be briefly noted throughout this section for both completeness and perspective. Readers are encouraged to refer to the ASRA practice advisories on these topics for details\textsuperscript{7,8} and should seek the most up-to-date versions of these works. Summary articles are available on the ASRA Web site (www.asra.com).

**Timely Recognition of Perioperative Nerve Injury**

Early recognition and appropriate stratification of suspected perioperative nerve injury into those that require emergent imaging and/or neurologic evaluation are of paramount importance to afford patients the best opportunity for full or partial recovery, especially in the case of neuraxial injuries. Nonetheless, our current advisory\textsuperscript{15} notes multiple barriers to appropriate recognition of perioperative nerve injury, including such factors as neurologic deficits being masked by sedation, concurrent analgesics, or continuous catheter use; the absence of ambulatory patient follow-up; or delayed recognition of sensorimotor deficits until after hospital discharge, which has been reported to occur in up to 90% of patients undergoing lower extremity arthroplasty.\textsuperscript{16,171} Delayed recognition is more likely to be associated with nonoperative causes of nerve injury, such as immobilization, dressing compression, infection, or inflammation. Such delays also confound the patient’s perception of onset. In the “blur” that accompanies typical perioperative events, patients can incorrectly report their symptoms as presenting immediately after surgery despite objective documentation of onset at 48 hours, as for example with peripheroperoneal nerve injury.\textsuperscript{172} The complexity of perioperative recognition, the absolute imperative in some cases to diagnose and treat emergently, and operators’ unique understanding of the expected consequences of their procedure, all speak to the advisability of direct, candid, and timely conversation between the anesthesiologist or pain physician and the neurologic consultant.\textsuperscript{15}

**Diagnosis and Treatment of Neuaxial Complications**

Certain signs and symptoms after neuraxial blockade should raise suspicion for perioperative nerve injury. Weakness that is
Anecdotal case reports and small case series suggest that neuraxial anesthesia and analgesia in patients with complex spinal canal pathology can be beneficial. However, careful consideration of the potential risks and benefits is necessary.

Because of the wide range and severity of possible spinal cord and vertebral column malformations, patients with neural tube defects may pose unique challenges to anesthesiologists. Despite the potential risks, neuraxial anesthesia and analgesia are often used in patients with preexistent spinal canal pathology, particularly in cases of congenital anomalies. However, an increased risk of new or progressive neurologic deficits is associated with some preexistent conditions, although the evidence supporting this practice is lacking.

Prior spine surgery is not a contraindication to the performance of neuraxial anesthesia or analgesia. However, a careful discussion regarding the potential risks and benefits of performing regional anesthesia in patients with preexistent neural compromise is strongly recommended.

Regional anesthesia may be technically easier to perform and more reliable than epidural techniques in patients who have previously undergone spine surgery. Patients undergoing neuraxial anesthesia or analgesia to the neuraxis may theoretically increase the risk of new or progressive neurologic deficits in patients with diabetic peripheral neuropathy (Class I).

Spinal Canal Pathology

Previous Spine Surgery

Prior spine surgery is not a contraindication to the performance of neuraxial anesthesia or analgesia. However, performing a regional technique, review of the patient’s radiologic imaging or the use of fluoroscopy could be useful to identify the optimal approach to the neuraxis (Class I).

Under most clinical circumstances, spinal anesthesia may be (a) technically easier to perform and (b) more reliable (ie, higher success rates) than epidural techniques in patients who have previously undergone spine surgery. Patients undergoing neuraxial anesthesia or analgesia after previous spine surgery do not seem to be at higher risk of new or progressive neurologic deficits (Class II).

Neural Tube Defects

Neural tube defects encompass a wide range of spinal cord malformations, including both open (eg, meningocele, meningo(myelo)cele) and closed (eg, spina bifida occulta, tethered spinal cord syndrome, diastematomyelia, dural ectasia) spinal dysraphisms. Patients with neural tube defects may have clinical or subclinical evidence of a preexisting neurologic deficit caused by neural compromise from the disease state (Class I).

Because of the wide range and severity of possible spinal cord and vertebral column malformations, patients with neural tube defects should undergo radiographic imaging to fully evaluate and define the extent of their disease state before considering neuraxial anesthesia or analgesia (Class II).

Anecdotal case reports and small case series suggest that the performance of neuraxial anesthesia and analgesia in patients with complex closed spinal dysraphisms (ie, tethered spinal cord syndrome or diastematomyelia) may result in new or progressive neurologic symptoms. However, definitive evidence supporting this practice is lacking (Class II).

Anecdotal case reports and small case series suggest that neuraxial anesthesia and analgesia may be used in patients with isolated spine bifida occulta (without associated tethered spinal cord syndrome or diastematomyelia) without an increased risk of neurologic injury. However, definitive evidence supporting this practice is lacking (Class II).

Peripheral Nervous System Disorders

Hereditary Peripheral Neuropathies

• Patients with diabetic peripheral neuropathy or previous exposure to chemotherapy (eg, cisplatin or vincristine) may have clinical or subclinical evidence of a preexistent peripheral neuropathy caused by neural compromise from the disease state (Class I).

• An abundance of animal data and limited clinical data support the concern that diabetic nerves are more sensitive to local anesthetics and perhaps more susceptible to injury. Therefore, peripheral and neuraxial blockade may theoretically increase the risk of new or progressive neurologic deficits in patients with diabetic peripheral neuropathy (Class II).

• When regional anesthesia is thought to be appropriate in patients with acquired peripheral neuropathy (eg, diabetic peripheral neuropathy or chemotherapy-induced neuropathy), consideration should be given to modify the anesthetic technique (ie, decreasing the concentration of local anesthetic, reducing the total dose of local anesthetic, eliminating or reducing the concentration of vasoconstrictors such as epinephrine) to minimize the potential additive risk (Class II).

• The use of ultrasound guidance may facilitate (a) perineural needle placement and (b) a reduction in the total dose (volume) of local anesthetic administered. However, clinical data demonstrating a reduction in neurologic injury with ultrasound guidance are currently lacking (Class II).

Inflammatory Neuropathies

• Patients with inflammatory neuropathies such as GBS and PSIN are at risk of new or worsening neurologic deficits during the postoperative period regardless of anesthetic technique (Class II).

• Neural compromise secondary to acute neuronal inflammation may be a relative contraindication to regional anesthesia. However, the existing literature can neither support nor refute this claim. Therefore, the decision to perform neuraxial or peripheral nerve blockade in patients with inflammatory neuropathies should be made on an individual basis after a thorough discussion of the potential risks and benefits with the patient (Class III).

CNS Disorders

• Patients with CNS disorders (eg, MS, PPS, ALS) may have clinical or subclinical evidence of a preexisting neurologic deficit caused by neural compromise from the disease state. Furthermore, it is not uncommon for patients with CNS disorders to experience worsening of their neurologic symptoms during the postoperative period regardless of the anesthetic technique (Class I).

• Anecdotal case reports and small case series suggest that neuraxial anesthesia and analgesia may be used in patients with stable CNS disorders. However, definitive evidence supporting this practice is lacking. Therefore, a careful discussion regarding the potential risks and benefits of performing regional anesthesia in patients with preexistent neural compromise is strongly recommended (Class II).

Spinal Canal Pathology

Previous Spine Surgery

Prior spine surgery is not a contraindication to the performance of neuraxial anesthesia or analgesia. However, before performing a regional technique, review of the patient’s radiologic imaging or the use of fluoroscopy could be useful to identify the optimal approach to the neuraxis (Class I).

Under most clinical circumstances, spinal anesthesia may be (a) technically easier to perform and (b) more reliable (ie, higher success rates) than epidural techniques in patients who have previously undergone spine surgery. Patients undergoing neuraxial anesthesia or analgesia after previous spine surgery do not seem to be at higher risk of new or progressive neurologic deficits (Class II).

Neural Tube Defects

more intense than expected, recurrent after initial resolution, progressive, and/or in an area inconsistent with the block (e.g., lower leg or foot weakness associated with a thoracic epidural) can be the first presenting symptoms of a significant neuraxial injury.36,173–175 Back pain is observed less frequently, whereas bowel or bladder symptoms are late. For those mass lesions amendable to emergent surgical decompression, full (40%–66%) or partial recovery is possible if decompression occurs within 8 to 12 hours of symptom onset, although a recent study challenges this assumption.61 The severity of neurologic deficit at the time of intervention also predicts outcome.176–178 Frequently noted in medicolegal claims36 is the failure of anesthesiologists to recognize and begin management of a neuraxial complication in a timely manner—all too often, neurologic deficits are wrongly attributed to the block itself. Inappropriate delays are all the more likely when unenlightened surgical or nursing personnel manage the patient in the absence of anesthesiologist expertise. When injury is suspected, magnetic resonance imaging (MRI) differentiates soft tissues, identifies coexisting spinal canal pathology, and locates an aberrantly placed catheter more effectively than does computerized tomography (CT). However, in the absence of immediately available MRI, an emergent CT scan can identify those space-occupying compressive processes most amenable to emergent surgical decompression (i.e., spinal abscess or hematoma).

Table 13 presents the characteristics of neuraxial injury presentation that may aid differential diagnosis. Epidural hematoma is associated temporally with needle/catheter placement or catheter removal and in 75% of cases will have a fulminant presentation within 24 hours.177 Conversely, spinal epidural abscess or meningitis may have an insidious presentation—a delay of several days

Peripheral Nerve Injury

Electrodiagnostic studies (EMG and nerve conduction studies) may help confirm neuropraxia with conduction block or define preexisting neurogenic injury. If the only sensory involvement is paresthesia, the diagnosis should be confirmed by CT or MRI. The diagnosis and treatment of neuraxial injuries are presented in Tables 14 and 15.

Diagnosis and Treatment of Peripheral Nerve Complications

Similar to neuraxial injuries, the diagnosis and treatment of PNIs should be approached urgently to rule out potentially correctable lesions, such as from extrinsic or intrinsic compression after the procedure, followed by indolent fever and back pain, followed by rapid progression to paralysis. Accurate diagnosis and therapy are important because spinal epidural abscess is a significant problem with a mortality rate of 15% in patients with a history of infection. Early diagnosis of epidural abscess is associated with severe disease when performed acutely. Axonal loss (prognostic) and the extent of a perioperative neurogenic injury will be better clarified by electrodiagnostic studies performed 3 wk after injury (Level I).

Table 14. Recommendations: Diagnosis of Perioperative Nerve Injury

These recommendations are intended to encourage optimal patient care but cannot ensure the avoidance of adverse outcomes. As with any practice advisory recommendation, these are subject to revision as knowledge advances regarding specific complications.

Neuraxial Injury

In the setting of neuraxial anesthesia, any concern of spinal cord dysfunction requires emergent neuroimaging (Level I).

Magnetic resonance imaging is the preferred imaging modality. However, imaging should not be delayed to arrange MRI or to get neurologic consultation. Computerized tomography or CT myelography are acceptable as initial imaging to exclude a compressive lesion (Level I).

Diagnosis of a compressive lesion (epidural hematoma or spinal epidural abscess) within or near the neuraxis demands emergent neurosurgical consultation for consideration of decompression (Level I).

Peripheral Nerve Injury

Neurologic consultation is recommended for complete nerve injuries (complete absence of nerve function), incomplete injuries with moderate to severe functional limitations, or progressive neurologic dysfunction (Level I).

An inflammatory postsurgical neuropathy should be considered if there are multifocal, progressive deficits, unexplained excessive pain despite standard perioperative analgesia and neurologic deficits developing after a period of return to neurologic baseline postoperatively. Neurologic consultation should be considered (Level II).

Electrodiagnostic studies (EMG and nerve conduction studies) may help confirm neuropraxia with conduction block or define preexisting disease when performed acutely. Axonal loss (prognostic) and the extent of a perioperative neurogenic injury will be better clarified by electrodiagnostic studies performed 3 wk after injury (Level I).

Levels of evidence are based on the 2011 Oxford construct. EMG indicates electromyography.
### TABLE 15. Recommendations: Treatment of Perioperative Nerve Injury

These recommendations are intended to encourage optimal patient care but cannot ensure the avoidance of adverse outcomes. As with any practice advisory recommendation, these are subject to revision as knowledge advances regarding specific complications.

- Outcomes for compressive lesions (epidural hematoma or spinal epidural abscess) are dependent on the severity of neurologic impairment and the duration of symptoms at the time of neurosurgical decompression. Most experts agree that neurologic recovery is improved with early decompression (<8–12 h from symptom onset in epidural hematoma and <36 h from symptom onset for spinal epidural abscess) and when the preoperative neurologic deficits are milder in severity (Level I).
- Neuropathic pain is reasonably treated pharmacologically (Level I).
- Functional deficits from neurological injuries should be rehabilitated in concert with rehabilitation specialists (Level II).
- Nerve lesions that fail to resolve 3–5 mo after initial neurologic evaluation should prompt consideration of consultation with a peripheral nerve neurosurgeon (Level II).
- If imaging rules out an operable mass lesion and spinal cord ischemia is suspected, practitioners should ensure at least normal blood pressure and consider inducing high-normal-range blood pressure. The efficacy of CSF pressure modulation via lumbar drains in anesthesia/interventional pain medicine–related spinal cord ischemia is unknown, but the technique is widely used to treat surgical spine ischemia and seems safe in the setting of ischemic spinal cord injury (Class III).
- The role of corticosteroids in anesthesia-related injuries is unknown. Corticosteroids may have a beneficial effect after direct spinal cord trauma and possibly trauma resulting from interventional procedures. However, the potential benefits for these patients should be balanced against the associated risk of corticosteroid-associated hyperglycemia, that is, hyperglycemia worsens brain (and presumably, spinal cord) ischemic injury. We do not recommend the use of corticosteroids for ischemic spinal cord injury. Definitive diagnosis and treatment are best determined in consultation with neurology or neurosurgery colleagues (Class III).

Levels of evidence are based on the 2011 Oxford construct.\(^{18}\)

---

Management of Chronic Pain After Perioperative Nerve Injury

A subset of patients who sustain perioperative nerve injury will develop chronic neuropathic pain. The pain medicine physician is often called on to provide long-term symptomatic management of these patients and to assume coordination of patient education, expectation, and physical therapy. New to this advisory are evidence-based recommendations for the care of these challenging patients, some of whom may have unanswered questions or unrealistic expectations consequent to suboptimal communication with various practitioners during the immediate postoperative episode.

Postoperative neuropathic pain syndromes may result from surgical injury, such as intercostal neuritis after thoracotomy, or may be consequent to neural blocks administered during the perioperative period. There are several considerations for when it might be appropriate to refer patients with persistent postsurgical pain to a pain medicine specialist—severe pain out of proportion to that expected from a specific surgical procedure; pain that limits patient function; or pain that is progressive, multifocal, and/or difficult to localize. Other signs that should prompt early referral are those consistent with chronic regional pain syndrome, such as neurologic impairment in an area remote from the regional block, surgery, or compression or physical signs such as allodynia, edema, or hyperhidrosis. Readers are referred to the supporting article’s\(^{15}\) detailed recommendations regarding stepwise pharmacologic therapies for these patients, as well as reasonable indications for the use of diagnostic nerve blocks, such as stellate ganglion block. The evidence for neuromodulation therapy is less conclusive; the European Federation of Neurological Societies supports the use of spinal cord stimulation for chronic regional pain syndrome,\(^{180}\) although there are no supporting studies specific to postsurgical neuropathic pain.

In summary, the diagnosis and treatment of neuraxial injuries demands emergent stratification of those injuries that may be amenable to surgical decompression. Although the management of PNIs is less urgent (particularly when sensory predominant), practitioners are reminded that severe, progressive, or difficult-to-localize deficits demand urgent neurologic consultation to exclude potentially treatable causes such as from compressive etiologies. If

### Postsurgical Inflammatory Neuropathies

Postsurgical inflammatory neuropathies were discussed previously in the preexisting neurologic disease section. When patients present with this symptom complex in the postsurgical period, urgent neurologic consultation is warranted.

---

(casts, dressings, compartment syndrome, visible hematoma, or occult perineural microhematoma). If a hematoma is suspected, urgent imaging or ultrasonography should be considered. Acute surgical injury should also be ruled out by engaging the surgeon in candid discussion regarding the possibility of nerve transection, excessive traction, or wayward ligatures. Indeed, I review reported that more than 90% of surgically explored iatrogenic nerve injuries were linked to intraoperative causes.\(^{182}\) The goal of timely consultation is to alleviate potentially correctable causes or nonsurgical or anesthesia-related etiologies, such as stroke. Once the need for immediate treatment has been ruled out, the diagnosis of PNI can proceed as directed by initial presenting symptoms (Fig. 3). Pure sensory deficits that occur within the territory of the peripheral block,\(^{74}\) or a classic compression point, for example, common peroneal nerve compression at the fibular head, can be observed and are expected to resolve within days to weeks. However, neurologic consultation should be considered when the deficit involves motor function, is progressive, is characterized by recrudescence of neural blockade, or is difficult to localize and/or reconcile with the expected distribution of the anesthetic block or surgery. Electrophysiologic studies for more severe or unclear cases are typically delayed for 2 to 3 weeks, when signs of Wallerian degeneration first appear. However, early electrophysiologic studies may be worthwhile to define preexisting pathology. Bilateral studies may be indicated if occult conditions are suspected to affect the nonoperative side. Such decisions are best made in consultation with a neurologist. When no or incomplete improvement has taken place by 3 to 5 months, consideration should be given for referral to a peripheral nerve surgeon. Recommendations for the diagnosis and treatment of PNIs can be found in Tables 14 and 15.

CONCLUSIONS

The Second ASRA Practice Advisory on Neurologic Complications Associated With Regional Anesthesia and Pain Medicine provides a number of updates to the 2008 advisory. New information has been presented on the incidence of nerve injury inherent to common elective orthopedic surgeries. The advisory contains updated information regarding the pathophysiology of neuraxial and peripheral nerve injury. New or expanded information is presented, particularly with regard to spinal canal pathology, blood pressure control during neuraxial anesthetics, neurotoxicity-related neuraxial injuries, transformaminal pain medicine procedures, and the advisability of performing procedures in anesthetized or deeply sedated patients. The advisory also expands recommendations related to the diagnosis and treatment of these disorders.

Our final conclusion is very similar to that made in 2008: “Neurologic complications associated with regional anesthesia and pain medicine are rare—particularly those complications that do not involve hematoma or infection. Understanding the pathophysiology and risk factors associated with neuraxial and peripheral nerve injury may allow anesthesiologists to minimize the number of adverse neurologic outcomes. Unfortunately, even with flawlss care of otherwise healthy patients by well-trained physicians, these complications are neither completely predictable nor preventable. This practice advisory offers a number of recommendations specific to common clinical scenarios encountered in everyday practice.”
